Notes for simulation of traffic flow on an arbitrary network of one-way single-lane roads with traffix lights at intersections.

Charles S. Peskin April 17, 2017 C = can index, nc = # f cars

i = i Wersechm inclex, ni = # fintersection

b = block mdex, nb = # of blocks

i1(b), i2(b) = indices of intersections connected by block b, ordered by the direction of traffic flow. (All blocks are one-way.)

nbin (i) = # of blocks eweriz intersection i

 $bin(i,j) = index f j^{th} block enterior intersection i$ <math>j=1...nbin(i)

nbout (i) = # fblocks leaving messeem i

bout (i, i) = index of jh block leaving onlessechn i
j=1...nbout(i)

Note that noin, bin can be derived from 12, and that nout, but can be derived from i1, as follows:

for i=1:ni pbin(i)=Sum(i2==i) nbout(i)=Sum(i1==i)end nbinmax=max(nbin) nboutmax=max(nbout) bin=Zelos(ni,nbinmax) bout=Zelos(ni,nboutmax) for i=1:ni bm(i,1:nbin(i))=find(i2==i) bout(i,1:nbout(i))=find(i1==i)end

As a check, it should be the care that

sum (nbin) = sum (nbout) = nb

Traffiz lights

At any given time, the traffiz light at Musering is green for exactly one of the blocks that enter that observed and red for all of the others entery that observed in

Let jgreenli) be an integer designating which block has the green light, where

 $1 \leq jgreen(i) \leq nbin(i)$

let S(b) be the state of the light at the end of block b, where S=0 denotes red and S=1 denotes green.

Granthe array jgreen, s can be set

 $S = 2e_{10}s(1, nb)$ $f_{10} i = 1: ni$ b = bin(i, jgreen(i))s(b) = 1

and

Geometric Mormation court the network of neads

xi/i), yi/i) = coordinates of Mersection i

L(b) = length of block b

(UX(b), uy(b)) = unit vector along block b m direction of traffic flow

Gren Xi, yi, we can find L, ux, uy as follows

ux = xi(i2) - xi(i1) uy = yi(i2) - yi(i1)

L = Syrt(ux.12 + uy.12)

ux = ux./L uy = uy./L

Cars on blocks

Let p(c) be the position of can c on whatever block it happens to be on, measured as distance from the start of the block. If can c is on block b, then

$$0 \le p(c) < L(b)$$

and the coordinates of can a are given by

$$\chi(c) = \chi_i(i1(b)) + p(c) * u\chi(b)$$

 $y(c) = y_i(i1(b)) + p(c) * uy(b)$

To access all of the cars on a block in order of decreasing p, we use the following linked-list data structure

first can (b) = index of first can an block b next can (c) = index of can immediately behind can c on the same block last can (b) = index of last can on block b

In all cases, an entry f D means that there is no such can. Thus next can (last can (b) = 0, and if block b is empty then first can (b) = 1 ast (ast can (b) = 0.

Entry of cars and choice of their destinations

Cars enter the roadway (from parking garages or parking spaces) at random times and locations. Let R be the rate at which This occurs. Then R has units of 1/(time. length). Choose the time step dt small enough that R*Lmax *dt << 1, where Lmax is the largest length of any block. Then we can make the approximetry that at most one car enters the roadway per block per time step. To decide Whether this happens and to choose the location p on the block if it does, we can do the following in each block b:

if (rand < dt * R* L(b)) nc = nc + 1p(nc) = rand * L(b)

When a car enters the roadway, it is assigned a destination. This can also be done randomly. Let bd(c) be the block on which the destination fres and let pd(c) be the position in that block, expressed as distance from the

Stant of the block. A simple way to make this choice is

bd(c) = 1 + floor(rand*nb)pd(c) = rand*L(bd(c))

but note that this choice grees equal weight to any block regardless of its buyth. To make the probability of choosing a block be properhimed to its buyth, we can use the method of rejection:

bd(c) = 1 + floor (rand*nb)

pd(c) = rand * Lmax

while (pd(c) >= L (bd(c)))

bd(c) = 1 + floor (rand*nb)

pd(c) = rand * Lmax

In this version we keep trying until we find a position that fits on the block, and this makes the block that is ultimately chosen be more likely to be a longer one. In fact, the probability of choosing a block is exactly proportional to its length, and pd is uniformly distributed over that length.

Steering a can to its destination (despite one-way streets!)

For this we need the Cartesian coordinates of the destination, which are given by

xd(c) = xi(i1(bd(c))) + pd(c)*ux(bd(c))yd(c) = yi(i1(bd(c))) + pd(c)*uy(bd(c))

When a can comes to an intersection, it can choose to enter any of the blocks leaving that intersection. The natural choice is the one that most nearly points towards the destination. To determine this, evaluate the vector from the intersection to the destination, and then the dot product of that vector with all of the unit vectors of the blocks leaving the intersection. The block that should be chosen is the one that maximizes this dot product (in the algebraic sense, i.e., choose the most positive or least negative vesult, not the one layest in magnitude).

According to the above prescription, if can c is at messection i, it should choose the next block b to enter in the following way

xdvec = xd(c) - xi(i) ydvec = yd(c) - yi(i)

dp=ux(bout(i, 1:nbout(i)))* xdvec +uy(bout(i, 1:nbout(i)))* ydvec

[dpmax,jb] = max(dp)

b = bout(i, jb)

In the above use of max, there are two outputs. The second one, ib, is the index of the clement of dp that has the maximum value.

The above steering algorithm works well for reasonable road networks, including cases in which it is necessary to go around the block to reach the destination because of one-way streets, but it is not guaranteed to work. For some roadway layouts and some destinations, a can can get trapped and go through a cycle of

blocks repeatedly by follows the above algorithm without ever reaching its destination. One way to avoid this is the flee can to remember the intersections it has been to and the choices it has made there, and never make the same choice twice at any given whersection. Another way that is easier to program is for the can to decide randomly at each intersection whether to follow the above algorithm whether to follow the above algorithm or to choose a random block. This can be programed as block.

if (rand < prchoice) jb = 1 + floor (rand * nbout(i)) b = bout (i, jb)

else

choose b by the method of maximizing the dot product as described above

Here prehoice is the probability that a random choice will be made.
